actually are initialized with Subclass objects. We could move through the array calling the draw() method of the Superclass for each element in the array. The overridden draw() methods in each Subclass shape could take care of drawing the shape the right way.

Therefore, to make this work, the only thing we have to remember is, Declare draw() in the Superclass, then, override draw() in each of the Subclasses to draw the correct Shape. The Run-Time Type Identification system will choose the correct subclass's draw() method dynamically i.e., on-the-fly at execution time. This is called dynamic method binding, and it makes Polymorphism work. Polymorphism relies on Dynamic Binding. Polymorphism, allows you to process Superclass objects in a Generic way. Only the parts of a program that need specific knowledge of the new class must be tailored specifically to the new class.
