supposed to be identified. You might be wondering about how it can be improved. Well, the best thing to do, you might have guessed it, is to simply tweak the model buildup code to change the learning algorithm, the testing to training set ratio, the learning rate and the number of images it samples through. You could even just run the entire code once again and check whether the system has produced any different accuracies for the objects since it now has 'learned' about the objects in the first simulation run.

Creating an inference device

Google uses the gRPC (Google's Remote Procedure Call) to create inference devices that are wrapped in the RPC protocol. This is used to help clients running the executions to share the access to a remote computer, either by establishing a docker channel or by linking them through a linux kernel.

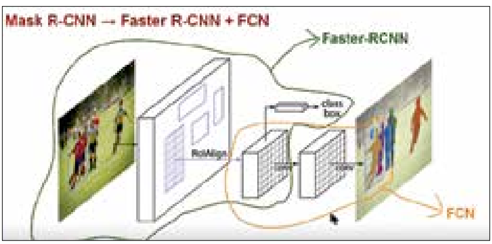

Image Resampling And Reassembling

This is done by creating a component known as a stub that is used by the TensorFlow architecture to serve models for inference.

In gRPC, a client application can link to remote channels through local networks almost as if they are local objects, making it simpler to create distributed services and splitting work among different systems.

A stub is a piece of code that converts parameters while a remote procedure call (RPC) is taking place. Since both the client and server may be in different addresses, the client parameters that are directed to the server and back should be converted so that the remote server can interpret it and treat it as a local function call. The stub code used below is reference frim the predict protobuf extension. You can even build a similar inference device using Intel hardware such as the Intel® Xeon® scalable processors or you could use Deep Learning accelerators based on the Intel® Arria® 10 FPGAs. Should you wish to perform inference on the edge, then there's always the Intel® Movidius ™ Neural Compute Stick that you can rely on.

All such setups allow for a cleaner and less hassle filled experience as the system breaks away chunks of the tasks to a number of smaller units that seamlessly work to deliver faster results. Clocking times and processing
