a ‘Turing Machine’. In other words, any general purpose programming language is capable of running any algorithm.

To achieve this, an emulator converts binary data written for execution on one machine to an equivalent binary form meant for execution on another machine.

Making an emulator is hard. It requires comprehensive understanding of how each hardware piece (such as audio and chips) works, handling their behavior and coding them into the emulation software as well.

Why do we need emulators?

Many of you may have heard about emulators, even if you haven’t used one yourselves. However, most of their use cases are limited to old Nintendo games played on them. That, of course, is a pretty handy utilisation of emulators, but a tiny drop in the ocean of an emulator’s capabilities.

In the software industry, for example, emulators are used to not only run programs that today’s operating systems refuse to run, but also design software for future hardware, so that once those hardware are available, they already have the needed software – saving lots of time.

Developers use this all the time. All the software development kits sent to them by companies often include an emulator. This can convey to the developer, say, what an Oculus Rift (or any other product they’re developing software for) feels like and what are the different constraints to be kept in
