

A Holographic Simulation

to replace the user's field of view while Augmented Reality aims to override it. It's not just the purpose that differs, but the underlying implementation of the technology also varies significantly. For example, VR primarily uses technology in closed spaces in order to engage the user while an AR device may use projections to build a holograph or some other 3D simulation in an open space with inputs and uses from the real world.

Furthermore, it's not just the projection that differs, but the interaction with user and surrounding differs majorly, too. VR essentially focuses on gauging user's action and altering the virtual world according to the input from sensors. It relies heavily on the sensory stimuli to emulate an environment that grips the user, ergo a large number and variety of sensors are required, varying from motion and audio detectors to gyroscopes, temperature monitors etc.

On the contrary, an AR system needs to gauge the physical world and simulate an artificial atmosphere that blends with the surrounding. It then overlays the surrounding with an augmented layer, which is interactive and can be manipulated digitally by user inputs. Hence, AR not only simulates a substructure of reality but processes real-time manipulations of the entire surrounding and implements the alterations to the simulated substructure only. Hence, if we conclusively compare AR and VR in terms of technological implementations, VR involves intensive rendering
