

quick as TN to shift from one colour to another, so the transitional phase is easily discernable on low-end panels. You'll notice blurring or a smoke trail behind quick moving objects on the screen. However, VA panels are cheaper than IPS and slightly expensive than TN, though if you were to step out to buy a monitor these days, it's quite likely that the two panels might end up costing the same.

As Fujitsu focused on MVA, Samsung decided to jump on the bandwagon and focus on PVA as an alternative to MVA. And since the development of the two subtypes started off early during the inception days, these two technologies have developed quite a lot of exclusive features on their own and can be considered to be completely distinct. Let's take a closer look at how MVA and PVA operate.

How does a VA display work?

MVA

Essentially in MVA panels, as the name suggests, there are multiple domains in which crystals are arranged and each domain is adjacent to another domain in which crystals are oriented differently. So when voltage is passed across the panel, as the crystals within one domain orient themselves to allow light to pass through, the adjacent domain's crystals will be at an angle that stops light from passing through. This increases the colour reproduction since stray light from adjacent domains are effectively curtailed.

Over the years, as MVA was improved upon the problem of poor response time continued to plague manufacturers. And when you're using MVA to

Multi-domain Vertical Alignment has a more uniform colour reproduction than TN
