

A Diagram of how polarized filter works

and then projected as a composite wave to the viewer. The viewer uses glasses where each eye has a different polarizing filter, so that only light with specific polarization passes through, thus creating two different images for each eye and achieving stereoscopy.

- d) **Active Shutter 3D system** - A.K.A Eclipse System is based on exactly what it sounds like. The screen/display keeps alternating between the images for each eye, and a shutter in the glasses alternately blocks the vision for the other eye. Although initially physical shutters were put to use, LCD shutter glasses are used to achieve this presently. The glass contains liquid crystals that only lets certain light through in sync with the display.
- e) **Autostereoscopy** - A.K.A Glassless 3D. This type of 3D displaying uses multiple methods, mainly parallax barrier (where an alternating line barrier in front of the screen blocks the screen at a specific angle thus allowing only one eye to see one specific part of the image) and lenticular lenses (replacing the line barriers and gaps of a parallax barrier with a 2D array of cylindrical lenses allowed certain viewing angles to see certain part of the image due to refraction)
- f) **Holographic Display** - Based on a light phenomenon called interference, holographic displays have achieved all four tenets of normal vision - binocular disparity (offset between the images perceived by the eyes), motion parallax (differently perceived speed based on the distance), accommodation and convergence. This technique also does not require any special
