

since Foundation, AppKit, UIKit etc. reported errors in a similar fashion. Not so much Swift 2.0 onwards. Apple introduced the try/catch mechanism, which is a staple in other, more popular languages, such as Java, C++, C#, JavaScript and others.

try/catch is a way of programming that means “try this thing, but if it fails do this other thing instead.” To create an error to throw, simply create an enum that derives from `ErrorType`. Later, a function or method is tagged with a `throws` keyword if it is required to throw one or more errors. Within the function, a series of `if...else` blocks can be used to throw any number of errors required. Now, while catching an error, the regular try-catch block offered in other languages has been scrapped in favour of a separate `do-catch` block. Multiple catch statements can be written in a fashion similar to a switch statement.

```

override func doLoad() {
    super.DoLoad()

    doStuff()
    print("3")
}

func doStuff() {
    print("5")
    defer { print("Passed through defer.") }
    print("2")
}

```

2. THE DEFER KEYWORD:

Extending on the way the try/catch block is used in other languages, Apple has also introduced an alternative to the commonly used `finally` keyword, which lets your app execute a certain block of

code, no matter what error is thrown before the code block. Swift 2 allows a block of code placed within the `defer` command to be executed right before you exit a method, irrespective of whether an error has been thrown. This form of scheduling makes `Defer` good for flushing a cache, writing a file or for any activity that needs to happen, regardless of the route your code is executed through.

3. COMPILE TIME CHECKED SELECTORS:

Taking an example from the official Swift blog, for a code snippet such as the one given here, though the code will compile without any problems, the usage of `addNewFireflyRefernce` in the `UIBarButtonItem` will cause the app to crash due to a single typo. Considering how common this is, Apple developers decided to add a useful functionality by removing strings for selectors and introducing the `#selector` syntax. According to the Swift documentation, “Using `#selector` will check your code at compile time to
