

or even the whims of the creator, but that doesn't mean you get to blame the reason and get away with it. Nope! So when it comes to Angular 2, there are also such things that you need to get yourself familiarised with - either to draw parallels to what you already know, or to get your fresh start right the first time. So, with that, let's dive into the basics of Angular 2.

Modules

The word module refers to small units of independent, reusable code. A typical module is a cohesive block of code dedicated to a single purpose. A module exports something of value in that code, typically one thing such as an object.

Angular 2 Module System:

When we code in Angular2 in TypeScript we use the two module keywords below:

- `Export--` Export module code.
- `Import--` Import module code.

Exporting Code:

We write our application as a collection of small modules. Our code exports each module using the 'export' keyword. For example, the code below is used to tell TypeScript that we are exporting class 'App' for use elsewhere.

- `export class App {...}`

Importing Code:

We have import statements to tell TypeScript to go get module code from somewhere. The 'somewhere' can be from someone else's module or from local code in the same project.

When we use import statements to go get code from someone else's module we specify the module name and the name of the item we wish to import. For example we are importing the Component from Angular:

- `import {Component} from 'angular2/core';`

When we import code from local code in the same project, we specify the module name but we also specify a file path (the './' in red below). This tells TypeScript that the code is in the same folder as the code that is going to use that module.

- `import {AppComponent} from './app.component';`
