

One Way data binding: Once you set the value it will not affect the View or Controller for further changes

Two Way data binding: Changes made in view will reflect in Controller. Changes made in Controller will reflect in View. Two way Data binding is Between View and Controller.

Explanation of the diagram:

- Change detector is associated with every component which keeps track of the bindings in its template.
- Change detection always flows from root component to leaf component.
- In order to reverse flow of (from leaf to root), event emitter is used in Angular 2.
- Event emitter can be used with each component to notify its parent about any property change, in this way parent is notified about the change.

Databinding in the works

- This is how the data flows in reverse direction known as two-way binding in Angular 2.0.

Variables can be used in component classes to store data and edit HTML in template of component to add binding. Now HTML is no longer static, it changes with data.
