

storage or the next-gen GPU – you change what you need, when you need (while compatible components are available in the market). This is simply not possible on an SoC. An SoC is a single package with all those components built-in. If you were to upgrade something, say RAM, on an SoC, you would need tools which can cut microscopic wires, remove dice from the package individually and solder the new RAM back on package without damaging other components. Oh, and you would need to close the package too! You see, upgrading a SoC is no common a feat and is almost never done. Current gen SoCs are etched on silicon so forget soldering altogether.

Liquid cooling on demand for PCs

The second area where the PC beats the SoC is heat-dissipation and performance. When you tax your PC with some serious compute job (like rendering an Adobe After Effects movie), it might run for hours to get the movie rendered. In the process, it will utilize the CPU (the processor) to its max, do a lot of read-writes on RAM and may put your GPU under pressure too. These are power-hungry devices which can heat up to 70-80 degree Celsius easily. Do that on an SoC and you would probably damage something inside it.

Each component in a PC can use heatsinks and liquid cooling to keep them working. SoCs contain all the components of the PC on a single chip
