

device, but we're going out on a limb here and guessing that the specifications won't be too harsh.

The ARCore SDK launched pretty recently and the two devices that supported the SDK at launch were the Google Pixel and the Samsung Galaxy S8. If you're beginning to see similarities between ARCore and Apple's ARKit, you're on the right track.

As for the SDK's functionalities:

Like Tango, ARCore focuses on three things:

- **Motion tracking:** It can use the phone's camera to observe the environment and store IMU sensor data. This allows ARCore to determine both the position and orientation (pose) of the phone as it moves. This also means that virtual objects you place also remain properly aligned
- **Environmental understanding:** ARCore can detect horizontal surfaces using the same feature points it uses for motion tracking. So objects you place virtually on a surface will actually behave like they're on a surface, and not float around aimlessly.
- **Light estimation:** ARCore can observe the ambient light in the environment and adjust it for virtual objects, making their appearance even more realistic.

You will notice that functionality wise, it's not too different from Tango, but the light estimation function is new and looks pretty cool. However, ARCore lacks the depth sensors that the Tango has. ARCore kind of tries to offset that by adjusting the lighting. ARCore works with Java/OpenGL, Unity, and Unreal and you can easily find documentation and guides to the same here: <http://dgit.in/gvartools>

Google Jump

Jump is Google's 360 degree camera software which can also film 3D. This makes it great for filming Virtual Reality content as well. The Jump camera rig consists of 16 separate cameras. Feed from each of the cameras is stitched together via the Jump Assembler to create a seamless 360 degree video.
