

the run time. In programming parlance, this kind of silencing is termed as Mocking. Imagine, you are testing a controller, then you would like to mock the event listeners so that they are not executed. You can concentrate on other tasks instead of wasting valuable time over unimportant modules. The framework ships with helper methods for mocking events, jobs and facades. Alternatively, you can make use of `fake()` method related to bus, event, mail, notification, queue and storage.

The `fake()` method included with the Bus facade can be used to prevent jobs from getting executed. If you use `fake()` method associated with the event facade, then you can prevent all event listeners from getting executed. If you don't want emails from getting delivered, you can use the `fake()` method under Mail facade on top of `assertSent()` method. The `assertQueued()` method can be used if the mails are to be queued for future delivery.

In the same way, you can use the same `fake()` method along with the facade associated with notification, queue and storage for performing the required tasks. You can prevent jobs from being queued and also can generate a fake disk in combination with `UploadedFile` class, which will simplify the testing process associated with the file uploads. You can also mock the Cache facade by using the `shouldReceive()` method. The important point to note is that the request facade should not be mocked but you can pass the values to the HTTP helper methods such as `get` and `post`. It is advisable to call the `Config::set` method instead of directly mocking the Config facade.

## Conclusion

Testing is an important element, which every developer should deal with properly while building either Windows or web-based applications. With Laravel, you can test application with helpful methods and commands. Due to the nature of the programming framework, you will have to apply coding. Please refer to the official Laravel testing documentation page at <http://dgit.in/Laraveltest> for detailed coverage. **d**
