

- `__bases__` – A possibly empty tuple containing the base classes, in the order of their occurrence in the base class list.

Use the print command to run the code at <https://dgit.in/ClassPy4> and the output will be something like what's shown at the link. As your code evolves, there might be objects that not get used later. As the usage decreases, the reference count of the object will keep decreasing and when it reaches zero Python collects it automatically and erases it to free up memory space, that can be re-purposed for other parts of the program.

Using classes and objects to build a program is just like using simple, smaller lego blocks to build a bigger structure

Data Structures Introduction

Data structures are an integral part of any programming language. At its core, a programming language is an algorithm and any algorithm processes data to achieve a specific goal. This data is stored in data structures. While processing the data, Python utilizes various data structures in a logical way to solve a specific problem. There are 4 most popular and in-built data structures- list, tuple, dictionary and set. Other data structures also include strings, arrays, queue and matrix.

List is a type of a compound data called sequence and one of the easiest and widely used too. You can do several things with a sequence like indexing, slicing, adding, multiplying, and checking for membership. In addition, Python has built-in functions for finding the length of a sequence and for finding its largest and smallest elements.

To create a list, simply define a list by writing the values separated by comma in square brackets. The data types need not be related or of the same category. E.g.

- `list1= ["Mumbai", "buildings", 25, 5000]`

This has created the list of Mumbai, buildings, 25 and 5000 and assigning the name list1. In a list, every value is assigned a position number starting
