

The if statement compares variables and process the code based on whether the condition is true or false. It runs a particular code if condition is true and another if its false. A simple example using `if` can be seen here: <https://dgit.in/IfPy>. When you run this code, it will first ask you to enter your year of birth. Once you enter the year of birth, it will run a series of commands on the input year and the fixed year given as 2018. The code will stop whenever any condition is satisfied. If the year of birth is less than 2018, it will run a simple subtraction operator and display the difference, if it's greater, the message 'Wrong value entered' will be displayed and if it's the same you will see the message, 'Welcome to the world kiddo'. The elif statement is optional and can be dropped to include only 2 possible outcomes.

Let's look at a slightly more complicated code combining list, operator and statements here: <https://dgit.in/IfPy2>. In this case, a list of names was created and the if statement was used to check if the name entered by the user matched any name in the list using the in function. If the values matched, Welcome message is displayed if not, 'You are not authorised to access' message is shown.

The while statement is a looping statement that causes the code to keep running until the condition necessary for the loop to stop is achieved, as shown here: <https://dgit.in/WhilePy>. So the program will only end when the user enters the number 23.

You can also use break statement to end a loop. In this case, when the user enters a particular value, the loop will break and the program will end. With the break statement, the else statement is ignored and the loop is forced to end even if the conditions are not met, as shown here: <https://dgit.in/BreakPy>. The output will always be 'Yes you are right' regardless of what the user enters- its an endless loop! But if the user enters 'quit', the loop will be immediately closed and the message, 'Done' will be displayed.

Functions, data structures, operators and statements are the building blocks of coding in Python and you should be thoroughly well versed with them. You can combine them in various ways and nest them in classes to create various objects.
