

```

• >>> s = "one two three one one two"
• >>> s.replace("one", "four")
• 'four two three four four two'

```

In order to split a string using a **delimiter** we can use the method `split(delimiter)` which returns a list of split substrings. Correspondingly, if we wish to join a bunch of strings using a **delimiter**, we can use `join(list)`, where `list` is the **list** of strings to be joined together and the **delimiter** is the string on which we are performing the operation.

```

• >>> s = "a-b-c-d-e-f"
• >>> list = s.split('-')
• >>> print(list)
• >>> ['a', 'b', 'c', 'd', 'e', 'f']
•
• >>> delimiter = '-'
• >>> delimiter.join(list)
• 'a-b-c-d-e-f'

```

List

A **List** is a sequential data type that contains a finite number of ordered objects and is one of the most widely used data structure. Since list is a sequential data structure every element in the list has an associated sequence number also known as the index. The indexes are incrementally assigned to elements starting from 0, where 0 is the index of the first element.

A list in a python program is represented as comma separated values contained in square brackets. It could contain heterogenous values, belonging to different types.

Python lists are similar to our everyday list.

```

• >>> l = [1, 2.2, None, 'abc'] # list assignment

```
