

In the first line, the function name is being defined with one input value, `sr_nos`, which has a variable length, hence the second argument is `*numbers`. So to define the argument `sr_nos`, you will have to create a class “list” which will be the definition of the name “`numbers`” and then use this class in the final output expression. When you call this function, you have to provide the values for the list class as shown here, along with the outputs that it will produce: <https://dgit.in/VarFunPy>.

One deviation from the standard syntax of a function is using a lambda function. This is also known as an anonymous function since it does not include the `def` keyword. So it's not a function in the traditional sense. They cannot contain commands or multiple expressions and return just one value in the form of an expression. Because there is no code embedded in the function, you cannot directly call the function to execute. You will instead need to use the `print` command and provide the definitions in the parentheses. Also unlike regular functions, they cannot access other variables except given in their parameters and in the global namespace. The syntax of lambda functions contains only a single statement, which is as follows –

- `lambda [arg1 [,arg2,.....argn]]:expression`

E.g.

- `say_hi = lambda arg1: arg1`

Pay attention to detail- its easy to miss out on providing a parameter and encountering an error
