

Now when using print, you can use any text string in place of “arg1”. The syntax to using the print command here is

- `print(say _ hi("Hello World"))`

This will give the output Hello World.

Lambda can be combined with other functions to produce multiple output strings. E.g.

- `def myfunc(n):`
`return lambda i: i*n`

And calling the function at <https://digit.in/Doubler> will give the output Doubled: 22. Tripled: 33. So what you have done is used a regular function to run real time one line code with lambda and multiple local variables. The defined function, myfunc, creates an anonymous function that multiplies variable i with variable n. Two more variables doubler and tripler were then created, which are assigned to the result of myfunc passing in 2 and 3 respectively. They are assigned to the generated lambda functions.

Variables

When building functions, you would have used variables in some cases. Let's understand a bit about variables and how they apply to functions. The scope of a variable determines the portion of the program where you can access a particular identifier. There are two basic scopes of variables in Python- Global variables and Local variables.

Variables that are defined inside a function body have a local scope, and those defined outside have a global scope. So local variables can be accessed only inside the function. The global variables are located outside the function and as such can be accessed at any time using simple commands like print. Let's take a look at an example

- `hello = "Hello Guest"# This is global variable.`
- `def hello _ user( name ):`
- `print ("Local : ", "Hello " + name)`

The variable “name” inside the function is a local variable. You can choose to define it just below the function name line. Now let's call the function and also use the global variable

- `hello _ user( "Digit" )`
- `print ("Global : ", hello )`

The first line will execute the function and give the result Local : Hello Digit and the second will call the global variable “hello” and
