

display `Global : Hello Guest`. Note that if you have defined the local variable, the output will display the value of the variable and ignore any value inputted when calling the function.

Methods

A method is also a function but it only resides within a class or an object. So it is dependant on the object and is implicitly passed the object on which it is invoked. The basic syntax of method is shown here: <https://dgit.in/BasicsPy> as is the way to print a list of names by creating a class and then using the function in it, as well as a way to call the function.

That code will give the output `Sanket, Mithun, Robert`. When executing, it first refers to the class under which the method is created and then calls the relevant function from it. So there could be 2 functions with the same but in different classes and they both can be called independently.

The code at <https://dgit.in/MethPy> will give the output `Sanket, Mithun` and `Sanket, Mithun` in two separate lines. You can also create as many method functions under one class as you want as shown here: <https://dgit.in/MethPy2> with the output as

- `Sanket, Mithun`
- `1101, 1102`

Similar to regular functions, there also are built-in methods. Let's take a look at one such method- `floor` and `ceil` (ceiling). Floor and ceiling will give a value of the next lowest or higher number from the specified integer, as shown here: <https://dgit.in/MethPy3>.

In this case, you have imported the math module (you will read about modules later). The output will read as

- `math.floor(300.16) : 300.0`
- `math.floor(300.72) : 300.0`
- `math.ceil(300.16) : 301.0`
- `math.ceil(300.72) : 301.0`

As stated earlier, functions are one of the most important tools in Python. As you have seen, they make life much easier and simpler for you as a coder. If you are going to use a set of code with a call feature repeatedly, just define it as a function and call it whenever required.
