

will show an error and terminate even if the rest of code is absolutely error free. This is where exception handling comes into the picture.

Try and Except

If you are writing a block of code that you are not sure about, you can use the try and except keywords to handles any possible errors. Let's take a look at a simple example. If the original code is

```
• print (10 * (1/1))
• print(4 + spam3)
• print(2+2)
```

You should recognise by this point that lines 1 and 3 are good but line 2 will throw up an error. So you would want to write line 2 using try and except keywords

```
• print (10 * (1/1))
•
• try:
•     print(4 + spam3)
• except:
•     print("Exception raised")
•
• print(2+2)
```

When you execute this code, the output will be

```
• 10.0
• Exception raised
• 4
```

Let's examine the `try...except` code block. The first statement try includes the block of code that you want to test. Next you have the `except` block which will be run if an error is encountered. If there is no error in the `try` block, it will simply run that code.

The `except` block is usually given a specific error to test and an output corresponding to it. You can also have multiple `except` codes and test for multiple error types. If there is no error type defined, as is the case here, it
