

will test for all exceptions which will significantly slow down your system. Also, it will not help you in identifying the root cause of the error. Let's see how multiple errors are tested using the above example

```
• try:
•     print(4 + spam3)
• except NameError:
•     print("NameError Exception raised")
• except ValueError:
•     print("ValueError Exception raised")
```

Executing this code will give the output, `NameError Exception raised`. If you remove the first `except` clause, you will be shown a `NameError` exception.

You can also include an `else` clause after all the `except` clauses. This clause is executed if the code in `try` raises no exceptions. In the above example, you can include the `else` clause after the `except ValueError:` line

```
• else:
•     print("Code is good")
•
• If the code in try cause causes no errors, e.g.
•
• try:
•     print(4 + 3)
• except NameError:
•     print("NameError Exception raised")
• except ValueError:
•     print("ValueError Exception raised")
• else:
•     print("Code is good")
•
• You will get the output
•
• 7
• Code is good
```

Lastly, you can use the `finally` clause. This clause means that this line of code will be executed irrespective of whether the `try` clause raises an error.
