

Typical relation between heat and MTBF.

stands for Mean Time Between Failures. It is the predicted time before a certain component will fail and is a measure of the component's reliability. Often, MTBF is calculated at a certain standard temperature. Above this temperature, the MTBF starts dropping i.e. the chance for failure starts increasing. Now imagine your average PC which is chock full of such components placed right next to each other. If they consistently run at a high temperature then the chances of each component failing individually starts to rise. When you consider that the average PC has a couple of thousands of such components, you realise how bad heat is for your PC.

Keep it cool to make it last

The simple solution to this problem is to keep your PC cool. Not only do you end up increasing your PC's lifespan but you also get better performance. Now before you jump the gun and order the most expensive cooler there is, hear us out first. When we say that you get better performance, it doesn't mean that cooling your PC provides incremental performance gains. Your average computer's processor has a built-in upper limit for per-
