

script, which will be C#, and then click on Create and Add. Or simply hit the return or enter key to confirm our selection. Unity will create, compile and attach this script to our selected game object. We should note, this way of creating a script will create that script asset on the root or top level of our Project view. We will need to move the asset in to the Scripts directory in order to maintain an organised Project view. If we select the script in our Project view we see a preview of the script asset in the Inspector, but this text is not editable. Let's open the script. We can do this a number of ways. When we are inspecting a game object using the script we can use the context sensitive gear menu. We can double click on the script asset in the Project view or we can use the Open button in the Inspector when we have the script selected in our Project view. This will open our script in our preferred script editor. First let's remove the sample code provided in the base script. Next let's think, what do we want to do with this script? We want to check every frame for player input and then we want to apply that input to the player game object every frame as movement. Where will we check for and apply this input? We have two choices. Update and Fixed Update. Update is called before rendering a frame and this is where most of our game code will go. Fixed Update on the other hand is called just before performing any physics calculations and this is where our physics code will go. We will be moving our ball by applying forces to the rigidbody, this is physics. So we will put our code in Fixed Update. What code to we need to write? We know we need input, but how do we find out more?

Adding a script component and choosing the language
