

Features such as plane detection and lighting estimation help make the AR experience seamless and immersive

Each of the SDKs have features that use proprietary tech. On the iPhone X, it is the TrueDepth camera whereas Android devices come abled with tech carried over from the now defunct Google Tango. However, it is still too early to say which one will surpass the other on the basis of these bare minimum fundamentals.

Other Key Functions and Features

While lighting estimation, plane detection and motion tracking are essential to measure the success of any good AR SDK, they will also require a few additional features integrated. Fret not, for both ARCore and ARKit do not disappoint. Both the platforms bring you these additional features that make AR development easy and authentic -

- They allow for 2D as well as 3D object tracking. This means that objects from the physical environment could be used as markers to trigger AR experiences for the end user.
- They will support smart glasses as and when the hardware becomes available in the market.
- They smartly incorporate anchors, which means AR content can be prevented from being lost if the user along with the device wander away from the area that is mapped by the app.
- They both allow for integration with third party tools. An important example here is their integration with the popular Unity game platform.
