

knowing which images to tag you in. Deep learning also accomplishes tasks like knowing how you like or dislike a service even before you have filled a customer satisfaction survey. It's creepy, but it's very real. The capabilities of both these seemingly similar terms are inherently different.

Basic or 'shallow' machine learning models have the tendency to age well over time, meaning that it becomes intuitive and smarter as time goes by. They will begin to perform functions better as they continue learning, but they often require external guidance. If a machine learning model comes back with a fallacious prediction, an engineer will most definitely need to step in and modify the algorithm to alter the inaccuracy and point it in the right direction. The key difference is not that deep learning will never return inaccurate results, instead, it is capable of identifying, on its own, if

Machine learning forms - supervised and unsupervised.

a prediction is accurate or not. Manual intervention being absent in many cases of deep learning is the key.

Machine learning trains a computer how to automate tasks, rather than programming it step by step. Deep learning does the same, but at a deeper level, by allowing more leeway to the absence of input and smarter predictions. Machine learning is typically split into two different forms - supervised learning - where the computer learns from examples in labelled data and unsupervised learning - where the computer categorises groups of seemingly similar data and pinpoints anomalies.

Machine learning often uses a technique called linear regression with gradient descent which allows it to accomplish simple tasks and make basic predictions like how the sales of ice-cream will vary according to the weather conditions outside. It makes these predictions based on a few data features and this process is relatively straightforward.
