

where the user simply inputs the object that has to be identified from the image and can see the progress of the training sets in real time.

Things to note

An important thing to remember is that all the simulations for the object detection algorithm will be measured regarding the loss function which is one of the creations of fuzzy logic. The loss function will be a major determinant to the accuracy of the model and the number of instances that the system properly identifies.

While all file types are accepted by the TensorFlow environment, using an SVG or PNG format is best suited for the system to detect the objects with perfect clarity. If the system can be trained to detect single images well

Neural Network Schema for Object Detection

enough, you can ultimately even combine images that can be fed as input to check how well the system learns.

Always run the sample simulations as an administrator to avoid the system from crashing if it doesn't have enough memory to work with. If such a situation arises, you can explicitly mention in the Python terminal to increase the space set apart for TensorFlow by setting the max stack value in the window to a higher value.

Alternatively, you can locate the python or tensorflow main folders and locate the runTensorFlow.ini file, right click it and edit it with notepad to change the max stack value.

When setting up the environment and uploading the statements with the import function, frequently save to make sure that the API has the required packages when you feel like running something large on it.

Before taking up any additional steps in coding and execution with the sample case datasets discussed in this chapter, make sure you've got the following lists crossed off your requirements:
