

You may be able to get the quality back when you run specific tests on the data. You can start by exploring “Trace Precedents”. The chances are high that there are problems with the code itself and a certain cell is creating all the problems. You can start with the first cell in the table and check why the errors are coming out in the first place. You can visit the Formulas tab and start venturing out.

You can also summarise all formulae being used in the sheet and then review it against the Evaluate Formula command. You can then enter them one by one and find the reason behind why the formula isn't working. You can also run the formulae against different data sets to check if the data is corrupt in some way.

When there are large data sets, there is always the chance of there being problems with execution. Even a single data point, hidden somewhere, can lead to overarching formula problems. Preserving the integrity of the data is key.

Default pre-sets and handling larger data

When handling larger sets of data, there is a chance that a legacy formula is interfering with a new formula that you designed. That's when most of the crashing takes place, and the sheet becomes corrupted with bad data. There is also the chance of an older pre-set interfering with a template that you decided to install.

When it comes to handling older datasheets its best to make copies of them and past as values only, this helps in preserving the data and having it remain relevant. Additionally, you also need to think about different compatibility issues that may arise. These issues could be related to how the data is handled and when there is enough insight present to solve that problem in the first place.

This is why you should focus on recovering the older information and forget about designing around the legacy files. On the other hand, you may have a newer format of Excel having a completely different template and font. Your existing file may not work in that environment due to a myriad of reasons. If your file was once opened by another software and then checked back by the Excel ecosystem you could have problems with pre-sets.

When it comes to larger data models, you need to split up the files before preparing complex algorithms. You can consolidate later, but a single workflow with a lot of information could crash repeatedly. Excel may not be able to provide the right insight at that point, and you may get an error without realising the source of it. **d**
