

we first need to be familiar with what exactly keyframes are and how are they used in animating still objects.

In the world of animation and filmmaking, a keyframe is a drawing which defines the initiation (starting) and conclusion (ending) points of any progressing smooth transition. They are also known as “frames”. This is because their position in time is measured on a strip of film in some frames.

It is not possible for an animator to draw every single frame or individually demarcate every tiny frame as it is a long and tedious process. Traditional animation also involves drawing in the most important or keyframes and then filling in the gaps with in-betweens. Keyframing is the simplest form of animation of a still 3-D object. This is because it is based on the idea that an object which has an initial state or condition, and which will

Inserting keyframes

be changing in position, colour, form, brightness, or any other property, to some final product form which is different from its initial conditions, will do so over a defined period. It takes the stance that if we only display the “key” frames, or important transition states, which descriptively summarise the transformation of the object – all other intermediate positions can be interpolated or figured out from these key (main) frames.

In Blender, we only need to set them, and the software automatically calculates the in-betweens. In the software, there are five primary ways of setting keyframes to animate a solid 3-D object.
