

data. And besides, writing codes to update, validate and test every layer of the topology is simply a terrible strain on the coder's wrist. This is why methods like random forests, logistic regression, Keras and xgboost become the go-to tools when things become too tough.

THE STEPS TO FUNCTIONAL APIS

Regardless of the environment used for building a standard functional API, there can be different models that will always be the default choices. If the project calls for working on non-numeric outputs, classification techniques like clustering, bagging, k means validation and decision trees should be used.

But once you tread onto regression territory, the techniques become more complex. Multivariate regression, SVMs, deep learning models become the norm.

As a starter, always remember to standardise and normalise the data so that it can be processed by the systems faster. Import the necessary libraries to set up the models. This also helps check for any redundancies and missing values that may affect model output.

Cross out any outliers in the dataset by graphical techniques and refine it by introducing filters. The next step should be to select the training and testing datasets for the model to be developed. A commonly suggested rule of thumb is a 60 to 70 per cent split between both. Or, use a cross-validation
