

physical device. This mode should be deployed when the application is ready for release.

Treatment and testing of Flutter apps

The treatment and testing of Flutter apps employ an array of features.

- **Unit test:** A unit test is essentially a single function test or method whose sole objective is to verify the correctness of the unit of logic that has been applied and this verification can only be done by subjecting the executed logic unit under a spectrum of conditions. External dependencies of the unit test are generally made to be understood using mock versions. Unit tests are not receptive to external user actions, and usually, don't read from disks or write to disks and are restricted to render on screen. Recipes provided in the form of utilising the knowledge of introduction to unit testing and verifying the mock dependencies using the Mockito variant.
- **Widget tests:** Widget tests, which are generally referred to as component test in the other UI frameworks; aim at verifying the UI looks of the widget and employing multiple classes to operate under the appropriate test environments that predict the approximate life cycle contextual reference to the particular widget.

A widget test is thoroughly detailed and more comprehensive than a unit test as it is responsive and interactive to the user actions and events are able to effectuate child widgets instantly and perform layout.

It can be also done under an imposed environment that utilises replaced condition instead of a full-blown UI system.
