

which employs the gradual fading of an image by the implementation of gradual opacity change through the GPU's inherent fragment shader.

Savelayer can also be warded off by implementing rectangles with rounded edges instead of the usual clipping rectangle.

### Effortless rendering of grids and lists

Lazy implementations like callback might be employed while building larger grids or lists. In that methodology, the visible portion of the screen can be established within the startup time.

### Construction and exhibition of frames in 16ms

Two separate threads exist for rendering and building and hence 16ms should be employed in both the actions while they are operating under the 60Hz frequency. If latency is a problem, then frames should be constricted to 8ms or even less and if missing intermediate frames or jankiness is a concern, those the separate stages for building and recording should be built in 16ms each.

If the frames are totally seamlessly operative in less than 16ms in profile mode, the performance issue should not be a concern. Though sudden hazards may appear, a frame should be conducted as fast as possible so as to:

- Improve battery life by optimising visual performance
- Run with the same speed and fluency in lower versions of the device where it might be installed
