

require different codes. For an application to be independent of platforms, it has to be designed separately for all of them. Most programmers stick to the two most highly used operating systems- Android, powered by Google, and iOS, powered by Apple.

Hence, it is understood that the burden to write codes for a mobile application can be quite heavy, and time-consuming. To overcome this issue, Google took a step forward to release a software that makes the work a lot easier. Known by the name of Flutter, this software is all the rage amongst programmers now. It basically builds applications that can run on Android and iOS, but the catch is- it does so using a common codebase. Flutter has its engine designed primarily in C++, a language that is heavily used and easily understood. Additionally, it uses Google's graphics library from Skia, thus providing a huge array of predefined attributes, like animation. While previously all of this needed to be done by the programmers manually, Google, with its software, has reduced the work considerably. Developers are also given the option to interact through Flutter, making the framework highly reactive, and the platform rich with collective knowledge.

Primary framework of the upcoming Google Fuchsia OS

Fuchsia works according to its own framework. It is very different from all its predecessors from Google and from other leading companies. It does not follow the conventional Linux model. Instead, Google took a bold step in actually designing something from scratch. It works differently,
