resembles a tree where the various instances of data have one thing common to them and are linked using that field. Each child record has only one parent, but one parent can have multiple child records. However, to be able to search for a record, it is necessary to go through every tree, which can get tedious. Also, hierarchical databases are not easily scalable.

- **Network Databases:** The network database has multiple records linked to multiple other record creating a cobweb of relations. Unlike the hierarchical database where a child record can have only one parent, here it is possible for a child record to have multiple parents.
- **Object-Oriented databases:** Object oriented databases uses small software entities called objects. These objects are stored in an object-oriented database and contained two types of information: a piece of data and instructions on what to do with the data.
- **Relational Databases:** In a relational database, every value in the database has an identity in the form of an attribute and record. The data value of each field is related to another table in the database. This makes the relational database very popular. Using it requires less or no training. A major advantage is that it is scalable, and data entries can be modified easily.

Relational Databases and Database Management Systems

Relational databases allow us to create relationships between every piece of information, so that it may be related to only itself or many tables within the database. Relational Database Management Systems (RDBMS) allows the users to store and manage large volumes of data. All the data is stored
