

- To solve and figure out design issues
- Monitor the performance of the database
- Identify server configuration problems such as application server, web server, database server, etc.
- Find hardware limitations such as network limitations, CPU maximization, memory limitation, and many more.

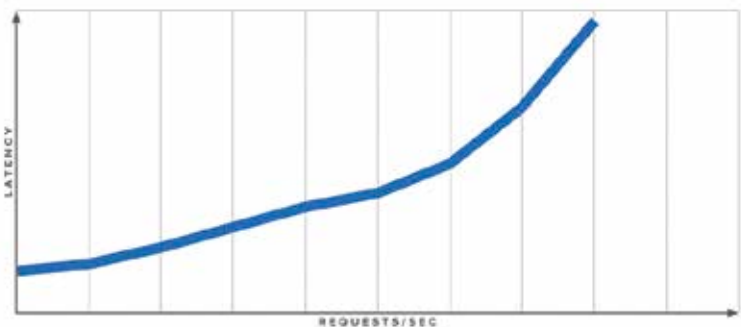

In short, load testing of a website can determine whether a website or application requires any software or hardware changes to make the performance faster.

Technical terms

Before moving towards the function and steps, we will be discussing a few technical terms that are related to the concept of load testing that you must be aware of. These are some technical terms you should know-

1. Latency

Latency is a term in web performance testing to measure the speed of response. It is estimated in milliseconds. It is also popularly known as response time. In short, it is how quickly a server of a website is responding to a user request. A reading with a short time span indicates a higher speed and response rate. Website developers should measure the latency from the users' perspective. Thus, latency is the time between request and response.

2. Throughput

Throughput evaluates a server's handling capacity. It measures how many users requests the server can handle during a specific interval of time. It is determined by the request per second ratio.
