

Kerberos can be defined as a secure third-party authentication protocol that doubles up as an identity-verifying proxy set-up as well. Post carrying out their authentication with Kerberos, users get to avail the tenets of data integrity and assured privacy at all times in their subsequent communications. The functionality of Kerberos is exclusively limited to offering a reliable authentication of servers and users alike on any particular network. It does not concern itself with auditing and authorisation functions. Hence, it is always advisable to implement Kerberos in conjunction with other security protocols that provide dedicated audit and authorisation services.

Workflow of Kerberos

OpenSSL

An open-source application of the TLS and SSL protocol, OpenSSL's primary objective is to facilitate an encryption transport layer in addition to the existing communications layer. Subsequently, it enables the communications layer to be entwined with numerous other services and network applications. The applications of OpenSSL are multifold. It is frequently used to encrypt authentication of clients operating over mail and to furnish certificates for use with software applications. These certificates can later be verified to validate the credentials of both the issuing authority as well as the receiving individual. Additionally, OpenSSL is also used to secure transactions of the likes of credit card payments and others that are web-based.
