The common convention is to make use of a name that is composed solely of capital or block letters. When you have to maintain several FreeBSD systems with each containing separate hardware, a good practice is to name it after the hostname of the machine in question. In retrospect, the format of the kernel configuration file is fairly straightforward. To begin with, every line has a keyword that is indicative of either an argument, a device, and a system, or a brief description.

Any text included post a `#` is regarded as a comment and is usually overlooked. Additionally, if you wish to do away with kernel support for a subsystem or a device, all you have to do is add a `#` at the beginning of the line representing that particular subsystem or device. If cannot comprehend a line, you are advised to neither remove nor add any `#` for that line. It is important to bear in mind that removing support for an option or a device is rather simple and can leave the system with a broken kernel. Hence, users are advised to be wary of this process. Further, an 'include' directive is also made available to the users for the purpose of configuration files. This directive enables the inclusion of another configuration file within the current one.

Troubles associated with building a kernel

Normally, there are four categories of trouble that usually take place while developing a custom kernel:

- **Config fails:** If the `config` directive fails, the incorrect line number gets printed.
