

Similarly, if you are using a modern web server, multiple connections can be required concurrently. However, the default value for concurrent connections in FreeBSD is 128, which will generally be too low. Hence, the `kern.ipc.soacceptqueue` can be used to increase the number of concurrent connections, recommended at a minimum of 1024.

In cases where the disk I/O causes performance issues in the system, the number of available vnodes might need to be increased. This can be done using the `kern.maxvnodes` variable. However, the amount of memory and storage available to you must be taken into account while changing this variable.

Similarly, variables such as `net.inet.ip.portrange` and `net.inet.tcp.inflight.enable` can be used to set several different network limits in FreeBSD.

Kernel Option in FreeBSD

Swap space

Regular and high capacity users of FreeBSD will very often encounter the need for excess swap space in the system. Swap space can be added in FreeBSD through two methods. You can either add swap space to a new hard drive, create a partition, or create a swap file in an existing partition in the system.

Among the two methods, adding a new hard drive is generally the method recommended, since it has been known to give better performance. A swap partition can be added to the system using `swapon`.
