

operating system. Thus, the first thing you need to understand about project management in Linux is the concept of multitasking.

Starting a Process

The two major processes that continuously run in Linux are foreground and background processes. When you start a process, it automatically initiates in the foreground and gives an output based on the user's input. Let's learn more about the two types of processes and what you can do with them.

The user or the programmer executes foreground processes or interactive processes. Users give input to the processes, and then the output is generated. While foreground processes run, new processes can't be initiated through the same terminal. Starting a foreground process is usually done through the "Is" command.

Another kind of process, known as background processes or non-interactive processes, is initiated by the system instead. These can also be managed by users and have a unique PID or Process Identifier. This is to create other processes within the same terminal. To start a background process, you need to add an ampersand (&) at the end of the command. An advantage of these processes is that you can run other commands and don't have to wait until the first completes.
