

when the internet is in the reckoning and when things are compromised at the level of say a software exploit, millions of people come under threat within seconds. However, most software are quick to patch in these exploits with updates and fixes. Here is where automatic updates come into play. If switched on, the software patch that has been issued would be installed as soon as it is released, and often before it is too late. But, if that is not the case, i.e., your system does not have automatic updates enabled; it might be too late before you actually notice the update amongst the ocean of notifications that our internet-connected devices feed us. At that point, chances are that the damage has already been done, and your device might be at risk.

Use the S

The Hyper Text Transfer Protocol Secure ensures that there is a secure connection established between your internet-enabled device and the server of the website you are accessing. While most of the services have moved on to adopting [HTTPS](#) as the default method of connecting, there are still some laggards who are yet to make this very important move

S in my name stands for secure

and are still stuck on [HTTP](#), which is not secure and lacks the measures of defence which [HTTPS](#) does. So, make sure that every webpage you visit has the address starting with [HTTPS](#), and if that's not there, add the S. If it works, well and good, but if it does not, make sure you leave the webpage as soon as possible, or do not input any sensitive data anywhere on there.
