

In summary, we have created a new environment named “ldm” in Python, installed all the necessary libraries for Stable Diffusion, activated the “ldm” environment, and changed the directory to a new folder. The final step is to navigate to the “C:\stable-diffusion\stable-diffusion-main\models\ldm\stable-diffusion-v1” folder in File Explorer, copy and paste the checkpoint file “sd-v1-4.ckpt” into it, rename the file to “model.ckpt” and wait for the transfer to complete.

With these steps, the installation of Stable Diffusion is complete and we are ready to use it. Python allows you to group coding projects into “Environments,” which are separate from each other, so you can load different libraries into different environments without worrying about conflicting versions. This feature is especially helpful when working on multiple projects on a single PC.

How to use stable diffusion?

To use Stable Diffusion, you must activate the ldm environment by typing “conda activate ldm” in the Miniconda3 window and pressing “Enter.” The “(ldm)” on the left indicates that the ldm environment is active. Note that you only need to enter this command once when you open Miniconda3, and the ldm environment will remain active until you close the window.

To generate images, we must first change the directory to “C:\stable-diffusion\stable-diffusion-main” by pasting “cd C:\stable-diffusion\stable-diffusion-main” into the command line.
