

```
i3.put_value();  
  
return 0;  
}
```

The output of this program is as follows:

```
object i2  
number: 378  
cost :78.6  
  
object i3  
number: 37  
cost:8.6
```

Now let us come to the explanation part of the program. First a class `i1` is defined. It contains two private variables, and two public functions. The private variable is a number and cost, while the two public member functions are `get_value` and the `put_value`. Within the class declaration, only the prototype of the function `get_value` is declared. This function is then defined outside the class and provides value to both the variables. Therefore, member functions can have direct access to private data members. Similarly, the `put_value` method is defined inside the class. This means that the function `put_value` behaves as an inline function. This function displays the values of the two private variables - number and cost. Within the `main()` function two objects `i2` and `i3` are created and the methods described above are called by these objects with proper argument.
