

insiders behind the trade we spoke to, a thumb rule that they follow is as follows: If you're partitioning packages, there is a simple equation that can be used to decide the required bandwidth.

Required bandwidth = number of visits per day x page views per visit x average page size x 30 (days in a month) x buffer.

The number visits per day is also known as average hits per day. You can start with a rough approximation and then calculate the bandwidth you'd need. Again, page views per visit is the average number of pages that viewers access per visit. Another quantity that you need to consider is the average page size. This quantity could vary depending on the number of images and their size and resolution on an average.

Finally, the basic rule of design irrespective of the platform or technology you work on requires you to allow for deviation from ideal cases. There needs to be room to accommodate an increment in the quantum of work. In our case, there needs to be space for unexpected increase in the number of visitors. If you have a web site for a doctor, then during seasons where swine flu is the most talked about subject, the web site should be able to handle the increase in search queries and page views and possibly even be able to handle download if they're available on the web site.

This buffer factor can be anywhere in the range of 1.1 – 3, depending on
