

For example, if an instance variable is assigned to an array in the class declaration, any instance of the class can (knowingly or unknowingly) manipulate this array, and cause changes that affect the other class instances. Such a manipulation can push a new item into the array or change the value of a specific array item.

You can declare a variable with a reference data type in the class definition:

```
members
• {
•   foo: [1, 2, 4] // All instances share this reference
type data structure
• }
```

To prevent the other instances from sharing the same data, initialize the actual value of the variable in the class constructor, not in the members section:

```
• construct: function()
• {
•   this.foo = [1, 2, 4]; // Each instance has with its own
data structure
• };
• members
• {
•   foo: null // Value to be initialized in the con-
structor
• }
```

In object-oriented programming, a concept of “access” or “visibility” of the members (or even classes) exists. The Web framework supports 3 access types:

▶ **public**

To be accessed from any class or instance. Member name cannot start with an underscore.

▶ **protected**

To be accessed only from derived classes or their instances. Member name starts with a single underscore.

▶ **private**

To be accessed only from the defining class or instance. Member name starts with a double underscore.
