Here, we use the each helper to loop over each item in the array we provided from the model() hook and print it inside an `<li>` element. You should now be able to see the list in your app.

CREATE A UI COMPONENT

As your Ember app grows, you'll find yourself reusing elements for multiple pages or even repeating them on the same page for your UI. The way Ember works makes it easy to modify your templates into reusable components. For instance, we can try making a component that will allow us to show a list of food at multiple places. Just like before, there's a generator for this one too.

```
ember generate component food-list
```

Copy the food template into the food-list component's template and edit it as follows:

```
<h2>{{title}}</h2>
<ul>
  {{#each dish as |edible|}}
    <li>{{edible}}</li>
  {{/each}}
</ul>
```

The things to notice here would be the dynamic `{{title}}` and the generic `|edible|`. Now, go back to the food template and replace its contents with the following

```
{{food-list title="List of Food" dish=model}}
```

Checking your browser now will show you that nothing has changed, however, you've switched your application to a component-sized version. As an exercise, you can try creating a list of desserts using a `desserts` route. If you reuse `food-list` correctly you should be done in no time at all.

CLICK EVENTS

When you're building an application for the web, you might want to be able to detect user actions like clicks, hovers and more. The application you've built so far has no way to do so. However, there are easy ways to do that in Ember. To start off, you need to add an `action` helper to your `food-list` component. You need to replace

```
<li>{{edible}}</li> with
<li {{action "showEdible" edible}}>{{edible}}</li>.
```

The purpose of the `action` helper is to add event listeners to elements and call named functions. The default is a `click` event listener, but the `action` helper can be used to listen for any element event. After the modification has been done, clicking the `li` element will call the `showEdible` function from the `actions` object in the `food-list` component. To handle this properly you need to add `showEdible` function to the `food-list` component file in an `actions` object. It should look like this:

```
import Component from '@ember/component';
export default Component.extend({
```

```
  actions: {
    showEdible(edible) {
      alert(edible);
    }
  }
```

Now, if you click the name of any food item on the list, an alert is generated with the name of the food item. Congratulations, your Ember app is now interactive.

BUILDING FOR PRODUCTION

You've built your application. You've verified that it works. Now is the time to deploy it to your users. For that, you need to run this command:

```
ember build --env production
```

This one command is responsible for packaging up all the parts of your application – JavaScript, templates, CSS, web fonts, images, and more. In the current example, Ember has been told to build for the production environment using the `--env` flag. This creates an optimized bundle that's ready to upload to your web host. Once the build finishes, you'll find all of the concatenated and minified assets in your application's `dist/` directory.

Checkout the Ember CLI Deploy add on for faster and reliable deployment into production. Also, if you intend to deploy to an Apache Web Server, first create a new virtual host for the application. With that, you're all set to go ahead with Ember.js
