light-years wide bubble became visible from the solar system, in which our planet is housed. Some of these star formations are Lupus, Ophiuchus, Pipe, and Corona Australis. Scientists were able to gather data related to stars and their formation in the 200-parsec range of the Sun.

As reported in the press release on the subject by the Centre of Astrophysics, Harvard and Smithsonian, commenting on what led to the formation of this bubble, Catherine Zucker, who is a co-author of the research paper, said, "We've calculated that about 15 supernovae have gone off over millions of years to form the Local Bubble that we see today."

It was surprisingly noted during the process of the research data gathered from the Gaia space observatory that the stars were being formed only on the surface of the Local Bubble and not inside it. There was a theory around this subject which has been floating around since 50 years ago, which stated that the supernova bubbles created from dying stars could create gases that would lead to the formation of newer stars. Now, that theory stands validated, opening the stage to the questions about the existence of other such bubbles across the universe. Given the number of stars being formed and going kaput in the universe every second, there might very well be a possibility that there are multiple similar bubbles across the universe, and we might come across another one in the future.

As it turns out, the Local

Bubble hasn't stopped growing. As reported in the paper, the bubble is growing at a speed of about 4 miles per second. This means in the time that it took to research and write this article, the bubble would have grown by about 57,600 miles. That's a lot! But the regions where stars are being formed are localised and can be zeroed down to certain clusters, which we in the night sky see as formations like Taurus. During the research, the scientists

A 3D spacetime animation, which can be found here: <https://dgit.in/1000ly-wide-bubble>, brings into perspective the locations of these star formations on the surface of the bubble.

There are a lot of questions that still remain unanswered, though. Catherine Zucker also talked about these questions and said, "Where do these bubbles touch? How do they interact with each other? How do superbubbles drive the birth of stars like our

Wow!

used the measurement of the 3D positions and motions of the stellar clusters to reconstruct the history of star formations located near the bubble. The clusters used by them shared a common characteristic, that none of them were older than 20 million years. They also observed the formation of each generation of cluster formation and put it into an interactive figure, to put into better perspective their evolutionary history. The interactive 3D figure can be found here: <https://dgit.in/if2>.

Sun in the Milky Way?" All of these are very legitimate queries, which, if and when they get answered, will give a whole new perspective to the understanding of space-related research and give scientists much more ways to look into the glittery specs in the sky. The operators of the spacecraft and the mission are also very hopeful of the possibilities that can be explored in our quest to understand the universe by using the data that is generated from the spacecraft.
